Keywords: Outage capacity Diversity channel Multiple Input Multiple Output (MIMO) Massive MIMO Rasyleigh fading

ABSTRACT

We consider the massive Multiple Input Multiple Output (MIMO) channel affected by independent and identically distributed Rayleigh fading, with linear processing at both transmitter and receiver sides to pursue full diversity, and analyze its outage capacity for large number of antennas. We first discuss the classical Single Input Multiple Output (SIMO) diversity channel that encompasses Maximal Ratio Combining (MRC) or Selection Combining (SC). For MRC, a numerical computation and a Gaussian Approximation (GA) are considered, whereas for SC an exact evaluation is presented. The analysis is then straightforwardly extended to the Multiple Input Single Output (MISO) diversity channel that encompasses Maximal Ratio Transmission (MRT) or transmit antenna selection. The general full diversity MIMO channel is finally considered, with optimal linear processing or simple antenna selection at both transmitter and receiver. If the number of antennas is sufficiently large on at least one side, the outage capacity of each considered diversity channel approaches that of a reference Additive White Gaussian Noise (AWGN) channel with properly defined Signal-to-Noise Ratio (SNR), which provides a performance benchmark. This conclusion is valid for large but realistic number of antennas compatible with the assumption of independent fading.

1. Introduction

Performance of wireless communication systems may be significantly impaired by fading effects, which can be counteracted by the well-known principle of diversity in time, frequency or space [1]. In particular, space diversity can be obtained by means of sufficiently spaced antennas at the transmitter or receiver, or both.

Space diversity is a classic technique that is acquiring further importance as a key enabler of modern wireless technology. Diversity techniques can be exploited for improving the performance of mobile Internet of Things (IoT) systems in fading environments [2]. Massive arrays of antennas are considered in modern 5G communications and beyond, see, e.g., [3] and references therein. Moreover, diversity is considered to fulfill the requirements of ultra-high reliability within a stringent latency constraint [4]. However, large diversity orders may be necessary for acceptable performance, as shown in [5,6] for Rayleigh fading.

Inspired by these recent contributions, we consider the massive Multiple Input Multiple Output (MIMO) channel, in which a

All rights reserved. large number of transmit and receive antennas are affected by independent and identically distributed (i.i.d.) Rayleigh fading. This model is, for instance, of interest in distributed massive MIMO systems, in which macrodiversity is achieved by means of several multi-antenna base stations [7,8]. Using the outage probability as performance measure, the downlink multi-user massive MIMO scenario is investigated in [9], whereas the uplink scenario is investigated in [10,11].

The MIMO channel can be operated at full diversity, i.e., by employing the multiple antennas to achieve maximum diversity gain and no multiplexing gain, in agreement with the fundamental diversity-multiplexing trade-off [1]. This MIMO diversity may be especially of interest in applications operating at low Signal-to-Noise Ratio (SNR), such as in low-rate (e.g., IoT) systems, where no multiplexing gain can be achieved by multiple antennas [1]. Another scenario where the massive MIMO diversity channel may arise is the so-called doubly massive MIMO, where both transmitter and receiver are equipped with large antenna arrays [12].

In this paper, we analyze the outage capacity of the MIMO diversity channel for large number of antennas on at least one side. The outage capacity is relevant in slow fading channels, in which the ergodic capacity is not a representative performance benchmark, as one may not be able to transmit codewords with arbitrarily small error probability and reasonably large blocklength, due to the non-zero probability that the channel is in

MIMO diversity channel

Fig. 1. MIMO diversity channel with N transmit and M receive antennas. Transmit beamforming and receive linear processing are considered.

deep fade for the entire codeword duration [1]. We provide a benchmark to the outage capacity of the massive MIMO diversity channel in terms of the capacity of the Additive White Gaussian Noise (AWGN) channel operated at a properly defined Signal-to-Noise Ratio (SNR). This benchmark is obtained for asymptotically high diversity order and proves useful to characterize the massive MIMO diversity channel for large but realistic diversity orders of practical interest.

We first consider the Single Input Multiple Output (SIMO) channel that encompasses Maximal Ratio Combining (MRC) or Selection Combining (SC). A closed-form expression of the outage capacity of the MRC diversity channel is not available, but a numerical evaluation is provided. A Gaussian Approximation (GA) valid for large number of antennas is also discussed and compared. On the other hand, an exact computation of the outage capacity is possible for the SC diversity channel. This analysis can be straightforwardly extended to the Multiple Input Single Output (MISO) channel with either Maximal Ratio Transmission (MRT) [13] or transmit antenna selection, here referred to as Selection Transmission (ST).

The general case of the MIMO channel operated at full diversity is finally analyzed. We assume optimal linear processing at both transmitter and receiver sides in order to achieve the maximum diversity order equal to the product of the number of transmit and receive antennas. We also consider the simple antenna selection scheme at both transmitter and receiver, here referred to as Selection Transmission and Combining (STC).

Our results show that, if the number of antennas is sufficiently large, the outage capacity of the diversity channel closely approaches the benchmark provided by the AWGN channel with properly defined SNR, but for a gap, under operational condition compatible with the independent fading assumption. Bounds and asymptotic results are also provided for the massive MIMO diversity channel. To the best of our knowledge, we are not aware of other work in the literature that discusses these bounds and asymptotic results for the outage capacity of the massive MIMO channel operated at full diversity.

The structure of this paper is the following. In Section 2, we review the MIMO, SIMO, and MISO diversity channels. In Section 3, we derive the outage capacity benchmarks for the considered scenarios. Numerical results are discussed in Section 4. Finally, concluding remarks are given in Section 5.

2. MIMO diversity channel

Consider the MIMO diversity channel depicted in Fig. 1. The encoded and modulated signal s(t) is precoded by the beamforming vector $\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \ldots, \alpha_N]^T$ and transmitted through N antennas, where the symbol T denotes the transpose operator. We assume the channel matrix \boldsymbol{H} has size $M \times N$ and independent frequency-flat slow fading gains $\{h_{ij}\}$. At the receiver, the signals received by the M antennas are linearly combined by the receive vector $\boldsymbol{\beta}^* = [\beta_1, \beta_2, \ldots, \beta_M]^{\dagger}$, where \dagger denotes the Hermitian transpose operator. The receive antennas are also affected by the AWGN vector $\boldsymbol{w}(t) = [w_1(t), w_2(t), \ldots, w_M(t)]^T$. The combined signal r(t) is used for demodulation and decoding. The MIMO diversity channel of interest in this work is the overall channel from s(t) to r(t).

The received signal can be expressed as

$$r(t) = \boldsymbol{\beta}^{\dagger} \boldsymbol{H} \boldsymbol{\alpha} \, s(t) + n(t) \tag{1}$$

where $n(t) = \boldsymbol{\beta}^{\dagger} \boldsymbol{w}(t)$ is the noise signal at the output of the receiver linear processor. The considered MIMO diversity channel with linear processing has diversity order *MN* [1].

Among various linear processing schemes in the literature, we assume ideal Channel State Information (CSI) and focus on two possible approaches. First, we consider optimal beamforming and receive combining to maximize the SNR at the output of the combiner, i.e., the SNR at the input of the demodulator. Assuming $\|\boldsymbol{\alpha}\| = \|\boldsymbol{\beta}\| = 1$ for signal and noise normalization purposes, it is well known that the SNR is maximized if $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are the principal right and left singular vectors of \boldsymbol{H} , respectively [1]. Under this assumption, it can be verified that the instantaneous SNR at the input of the demodulator can be expressed as [1]

$$\gamma_{\rm m} = \rho \sigma_{\rm max}^2 \tag{2}$$

where ρ is the SNR on a single unit-gain link and σ_{\max} is the largest singular value of **H**.

Another possible approach, referred to as Selection Transmission and Combining (STC), selects the transmit–receive antenna pair which exhibits the maximum instantaneous SNR. The SNR at the output of the combiner is therefore

$$\gamma_{\rm s} = \max_{i,j} \gamma_{ij} \tag{3}$$

where γ_{ij} is the SNR on the communication link between the *j*th transmit antenna, used at full power, and *i*th receive antenna (j = 1, 2, ..., N and i = 1, 2, ..., M). This approach is described by the linear processor with beamforming vector $\boldsymbol{\alpha}$ and receive combiner $\boldsymbol{\beta}$ characterized by just one unitary element each, whereas all other elements are zero.

The fading gains are assumed i.i.d. and to follow the Rayleigh model. The assumption of independent fading can be justified for massive antenna arrays of practical interest. As an example, if we assume that antenna elements are spaced by half wavelength to observe i.i.d. fading gains and consider a carrier frequency $f_{\rm c} = 5$ GHz, i.e., a wavelength $\lambda = c/f_{\rm c} = 6$ cm, where $c = 3 \cdot 10^8$ m/s is the propagation speed, antenna elements must be spaced at least by 3 cm for independency. Therefore, a massive square array of $10 \times 10 = 100$ antenna elements has dimension of approximately 30×30 cm and may be feasible and realistic in several applications¹ [14]. As other illustrative examples in the sub-6 GHz bandwidth, in [15], an antenna array with $3 \times 6 = 18$ elements, of approximate size 10×20 cm, is designed to operate at 4–4.7 GHz. In [16], the designed antenna array has $4 \times 4 = 16$ elements, approximate size 10×10 cm, and operates at 5.65 GHz. Due to their limited sizes, both can be used in low-rate applications, e.g., IoT, to approach a MIMO scenario with a few tens of antennas per side.

By direct extension of the results in [17], relative to the classical SC for the SIMO channel, the average SNR at the output of the receiver combiner in STC has the following closed-form expression for i.i.d. Rayleigh fading

$$\overline{\gamma}_{s} = \overline{\gamma} \sum_{\ell=1}^{MN} \frac{1}{\ell}$$
(4)

where $\overline{\gamma} = \mathbb{E}\{\gamma_{ij}\}$ is the average SNR on a single link at full power. In the next subsections, we discuss the special cases of SIMO and MISO channels.

2.1. Receive diversity (SIMO)

In the case of a single-antenna transmitter, N = 1, the system in Fig. 1 collapses into a standard SIMO system with receive diversity and M receive antennas. This scenario may be representative of uplink communications between single-antenna users and a multi-antenna base station.

In this case, $\boldsymbol{\alpha} = 1$ and the optimal linear combination at the receiver is MRC, i.e., $\boldsymbol{\beta} = \boldsymbol{h}/\|\boldsymbol{h}\|$, where $\boldsymbol{h} = [h_1, h_2, \dots, h_M]^T$ is the vector of channel coefficients. It is well known that the SNR at the output of the maximal ratio combiner is [1]

$$\gamma_{\rm m} = \sum_{\ell=1}^{M} \gamma_{\ell} \tag{5}$$

where γ_{ℓ} is the SNR on the ℓ th receive antenna, i.e., diversity branch. Its average value is

$$\overline{\gamma}_{\rm m} = \sum_{\ell=1}^{M} \overline{\gamma}_{\ell} \tag{6}$$

which reduces, for i.i.d. fading, to $\overline{\gamma}_{m} = M\overline{\gamma}$, with average branch SNR $\overline{\gamma} = \mathbb{E}\{\gamma_{\ell}\}$.

For N = 1, the STC approach (3) becomes the well-known SC, i.e., the combiner selects the signal of the diversity branch which

exhibits the maximum instantaneous SNR. The SNR at the output of the selection combiner is therefore

$$\gamma_{\rm s} = \max\{\gamma_1, \gamma_2, \dots, \gamma_M\} \tag{7}$$

and its average has the following closed-form expression for i.i.d. Rayleigh fading [17]:

$$\overline{\gamma}_{s} = \overline{\gamma} \sum_{\ell=1}^{M} \frac{1}{\ell}.$$
(8)

2.2. Transmit diversity (MISO)

In the case of a single-antenna receiver, M = 1, the system in Fig. 1 collapses into a MISO system with transmit diversity and N transmit antennas. This scenario can be representative of downlink communications between a multi-antenna base station and single-antenna users.

In this case, $\boldsymbol{\beta} = 1$ and the optimal linear processor at the transmitter is MRT, i.e., the beamforming vector $\boldsymbol{\alpha} = \boldsymbol{h}^*/\|\boldsymbol{h}\|$. By similar arguments as for MRC, the SNR at the output of the combiner can be shown to have a similar formulation as in (5), i.e.,

$$\gamma_{\rm m} = \sum_{\ell=1}^{N} \gamma_{\ell} \tag{9}$$

where γ_{ℓ} is the SNR received by the ℓ th transmit antenna used at full power [1]. The average value of (9) is

$$\overline{\gamma}_{\rm m} = \sum_{\ell=1}^{N} \overline{\gamma}_{\ell} \tag{10}$$

which reduces, for i.i.d. fading, to $\overline{\gamma}_{m} = N\overline{\gamma}$, with $\overline{\gamma} = \mathbb{E}\{\gamma_{\ell}\}$.

For M = 1, the STC approach (3) reduces to the well-known ST, which operates as SC, but at the transmitter side. In particular, the SNR at the output of the combiner is

$$\gamma_{\rm s} = \max\{\gamma_1, \gamma_2, \dots, \gamma_N\} \tag{11}$$

with average value for i.i.d. Rayleigh fading:

$$\overline{\gamma}_{s} = \overline{\gamma} \sum_{\ell=1}^{N} \frac{1}{\ell}.$$
(12)

3. Outage capacity analysis

The outage capacity C_{ε} of a slow fading channel is defined as the maximum achievable rate such that the outage probability is less than ε [1].

We define the following function

$$C(\gamma) = \log_2(1+\gamma) \tag{13}$$

which describes the capacity per unit bandwidth of the bandlimited AWGN channel operating at SNR γ . The outage capacity per unit bandwidth can be expressed as [1, Chap. 5]

$$C_{\varepsilon} = C(\gamma_0) = C(F^{-1}(\varepsilon)) \qquad b/s/Hz$$
(14)

where $\gamma_0 = F^{-1}(\varepsilon)$ is the SNR outage threshold, $F(\cdot)$ is Cumulative Distribution Function (CDF) of the SNR, and $F^{-1}(\cdot)$ is its inverse. This expression is valid for the diversity channels considered in Section 2, provided $F(\cdot)$ is the CDF of the SNR at the input of the respective demodulator.

In the following, we consider the different scenarios (SIMO, MISO, MIMO) and derive capacity benchmarks for the resulting diversity channels in terms of the reference AWGN channel with suitable values of SNR. We begin with the standard SIMO case

¹ At this carrier frequency, larger antenna arrays can also be realistic. For example, an antenna array with $100 \times 100 = 10^4$ elements would have size of 3×3 m and could still be considered feasible for cellular base stations.

Fig. 2. Illustrative example of the CDF (15) for $\overline{\gamma} = 10$ dB and various values of *M*. Values of γ_0 corresponding to an outage probability $\varepsilon = 0.1$ are highlighted.

and, then, extend the results to the other cases. To get insights, we also concentrate on the high and low SNR regimes, since the impact of fading may depend very much on the operating regime. In particular, at high SNR the difference between the outage capacity of the investigated diversity channel and the capacity of the relevant reference AWGN one is useful, whereas at low SNR the ratio between these quantities may be more convenient.

3.1. SIMO

3.1.1. Analysis for MRC

In MRC with i.i.d. branches subject to Rayleigh fading, the SNR γ_m in (5) at the output of the combiner has chi-square distribution with 2*M* degrees of freedom [1]. Therefore, the outage probability can be expressed in terms of the CDF of γ_m in (5) as

$$\varepsilon = F(\gamma_0) = 1 - e^{-\gamma_0/\overline{\gamma}} \sum_{\ell=0}^{M-1} \frac{1}{\ell!} \left(\frac{\gamma_0}{\overline{\gamma}}\right)^{\ell}.$$
 (15)

Since (15) does not admit exact inversion, the computation of the outage capacity $C_{\varepsilon}^{\text{MRC}}$ can be pursued numerically, as it is done in Section 4. An illustrative example of the CDF (15) for $\overline{\gamma} = 10 \text{ dB}$ and various values of *M* is shown in Fig. 2. Values of γ_0 corresponding to an outage probability $\varepsilon = 0.1$ are highlighted.

In order to get insights in the behavior of the outage capacity for large *M*, we consider a GA of the random variable (5) by the central limit theorem as $\gamma_m \sim \mathcal{N}(M\overline{\gamma}; M\overline{\gamma}^2)$, where $\mathbb{E}\{\gamma_m\} = M\overline{\gamma}$ and var $\{\gamma_m\} = M\overline{\gamma}^2$, as it can be easily verified. Hence, the outage probability can be approximated as

$$\varepsilon = F(\gamma_0) \simeq 1 - Q\left(\frac{\gamma_0 - M\overline{\gamma}}{\sqrt{M}\overline{\gamma}}\right)$$
(16)

where Q(x) is the tail function of a standard Gaussian random variable. This approximation can be inverted as

$$\gamma_0 = F^{-1}(\varepsilon) \simeq \overline{\gamma} \left[M - \sqrt{M} Q^{-1}(\varepsilon) \right]$$
(17)

where $Q^{-1}(\cdot)$ is the inverse of $Q(\cdot)$ and the symmetry $Q^{-1}(1 - \varepsilon) = -Q^{-1}(\varepsilon)$ is used. Using (17) in (14), one obtains the following high-order-diversity approximation of the outage capacity

$$C_{\varepsilon}^{\text{GA}}(\overline{\gamma}) = C\left(\overline{\gamma}\left(M - \sqrt{M}Q^{-1}(\varepsilon)\right)\right) \qquad \text{b/s/Hz.}$$
 (18)

Since the threshold SNR $\gamma_0 \ge 0$, from (17) the condition $M \ge [Q^{-1}(\varepsilon)]^2$ arises. This means that the approximation (18) for the outage capacity is defined for $M \ge [Q^{-1}(\varepsilon)]^2$. As shown by the numerical results in Section 4, this condition also affects the quality of the approximation, as lower values of ε require larger values of M for similar accuracy.

Considering now a reference AWGN channel at the average branch SNR $\overline{\gamma}$, the resulting capacity difference can be expressed as

$$C_{\varepsilon}^{\text{GA}}(\overline{\gamma}) - C(\overline{\gamma}) = \log_2 \frac{1 + \overline{\gamma} \left[M - \sqrt{M}Q^{-1}(\varepsilon) \right]}{1 + \overline{\gamma}}$$
(19)

which grows unboundedly for increasing values of M and any fixed values of $\overline{\gamma}$ and ε . Note that (19) can become quite large for practical values of M such that the i.i.d. fading assumption is still realistic.

By similar arguments, the ratio

$$\frac{C_{\varepsilon}^{\text{GA}}(\overline{\gamma})}{C(\overline{\gamma})} = \frac{\log_2\left(1 + \overline{\gamma}\left[M - \sqrt{M}Q^{-1}(\varepsilon)\right]\right)}{\log_2\left(1 + \overline{\gamma}\right)}$$
(20)

grows unboundedly for increasing values of *M* and fixed values of $\overline{\gamma}$ and ε .

The growth rate of (19) and (20) can be shown to be logarithmic in the number of antennas. However, a more interesting viewpoint can be obtained excluding the so-called array gain of MRC from the analysis [1]. Recall that the array gain is defined as the SNR gain provided by diversity in the absence of fading, i.e., when all the branches are affected by AWGN with deterministic SNR $\overline{\gamma}$. According to (5), the SNR in MRC and the AWGN channel is $\gamma_{\rm m} = M\overline{\gamma}$. Since a similar relation holds for the average SNR in i.i.d. fading, $\overline{\gamma}_{\rm m} = M\overline{\gamma}$, we can exclude the array gain from the analysis by considering the capacity difference with respect to the reference AWGN channel with SNR $\overline{\gamma}_{\rm m}$. Using $\overline{\gamma} = \overline{\gamma}_{\rm m}/M$ in (19), we have

$$C_{\varepsilon}^{\text{GA}}(\overline{\gamma}_{\text{m}}) - C(\overline{\gamma}_{\text{m}}) = \log_2 \frac{1 + \overline{\gamma}_{\text{m}} \left[1 - \frac{1}{\sqrt{M}} Q^{-1}(\varepsilon) \right]}{1 + \overline{\gamma}_{\text{m}}}.$$
 (21)

For increasing values of *M*, the term $Q^{-1}(\varepsilon)/\sqrt{M}$ tends to 0 for any fixed value of ε . Therefore, for high-order diversity, the (approximate) outage capacity with MRC approaches from below that of the reference AWGN channel with SNR $\overline{\gamma}_{\rm m}$. Hence, the capacity of this AWGN channel with SNR $\overline{\gamma}_{\rm m}$ provides a benchmark to the outage capacity of the massive SIMO diversity channel.

At high SNR specified by the conditions $\overline{\gamma}_{\rm m} \gg 1$ and $\overline{\gamma}_{\rm m}(1 - 1/\sqrt{M}Q^{-1}(\varepsilon)) \gg 1$, the second terms in the numerator and denominator of (21) become dominant and, therefore, one can approximate this capacity gap for high-order diversity as

$$C_{\varepsilon}^{\text{GA}}(\overline{\gamma}_{\text{m}}) - C(\overline{\gamma}_{\text{m}}) \simeq \log_{2} \frac{\overline{\gamma}_{\text{m}} \left[1 - \frac{1}{\sqrt{M}} Q^{-1}(\varepsilon) \right]}{\overline{\gamma}_{\text{m}}}$$
$$\simeq \log_{2} \left[1 - \frac{1}{\sqrt{M}} Q^{-1}(\varepsilon) \right]$$
$$\simeq -\frac{1}{\sqrt{M}} \frac{Q^{-1}(\varepsilon)}{\ln 2}$$
(22)

where the second approximation holds because $\ln(1 + x) \simeq x$ for $|x| \ll 1$. This gap tends to zero from below as $M^{-1/2}$ for increasing values of *M*. Note that the high-SNR condition $\overline{\gamma}_m(1 - 1/\sqrt{M}Q^{-1}(\varepsilon)) \gg 1$ is well behaved for large *M*, since if it is satisfied for some *M*, it is verified even better for larger values of *M*.

By similar arguments, using $\overline{\gamma} = \overline{\gamma}_{\rm m}/M$ in (20) the capacity ratio

$$\frac{C_{\varepsilon}^{\text{GA}}}{C(\overline{\gamma}_{\text{m}})} = \frac{\log_2\left(1 + \overline{\gamma}_{\text{m}}\left[1 - \frac{1}{\sqrt{M}}Q^{-1}(\varepsilon)\right]\right)}{\log_2(1 + \overline{\gamma}_{\text{m}})}$$
(23)

approaches 1 for increasing values of *M*. Again, this conclusion indicates that $C(\overline{\gamma}_m)$ describes a benchmark to the outage capacity. At low SNR specified by the conditions $\overline{\gamma}_m \ll 1$ and $\overline{\gamma}_m(1-1/\sqrt{M}Q^{-1}(\varepsilon)) \ll 1$, the approximate ratio is

$$\frac{C_{\varepsilon}^{\text{GA}}(\overline{\gamma}_{\text{m}})}{C(\overline{\gamma}_{\text{m}})} \simeq 1 - \frac{1}{\sqrt{M}} Q^{-1}(\varepsilon).$$
(24)

As the low-SNR condition is also well behaved for increasing M, we can conclude that the approximation (24) approaches 1 from below as $M^{-1/2}$.

3.1.2. Analysis for SC

In SC with i.i.d. branches subject to Rayleigh fading, the outage probability can be expressed as

$$\varepsilon = F(\gamma_0) = \left(1 - e^{-\gamma_0/\overline{\gamma}}\right)^M \tag{25}$$

which can be inverted as

$$\gamma_0 = F^{-1}(\varepsilon) = \overline{\gamma} \ln \frac{1}{1 - \varepsilon^{1/M}}$$
(26)

where $F(\cdot)$ and $F^{-1}(\cdot)$ are now the CDF of the SNR γ_s in (7) and its inverse, respectively. The outage capacity is then expressed in terms of (13) as

$$C_{\varepsilon}^{\rm SC}(\overline{\gamma}) = C\left(\overline{\gamma} \ln \frac{1}{1 - \varepsilon^{1/M}}\right) \quad b/s/Hz \tag{27}$$

and the difference with respect to that of the reference AWGN channel with SNR $\overline{\gamma}$ is

$$C_{\varepsilon}^{\rm SC}(\overline{\gamma}) - C(\overline{\gamma}) = \log_2 \frac{1 + \overline{\gamma} \ln \frac{1}{1 - \varepsilon^{1/M}}}{1 + \overline{\gamma}}$$
(28)

which grows unboundedly as *M* increases for any fixed values of $\overline{\gamma}$ and ε . In fact, using the first-order Taylor series expansion $1 - \varepsilon^x \simeq -x \ln \varepsilon$ about $x \simeq 0$ one has

$$\lim_{M \to +\infty} \ln \frac{1}{1 - \varepsilon^{1/M}} = \lim_{M \to +\infty} \ln \left(\frac{M}{-\ln \varepsilon} \right) = +\infty$$
(29)

since $-\ln \varepsilon \ge 0$.

In order to analyze the behavior of (28) for large diversity order, one can consider a high-SNR regime, i.e., $\overline{\gamma} \gg 1$ and $\overline{\gamma} \ln(1/(1-\varepsilon^{1/M})) \gg 1$. Note that, for a given ε , the second high-SNR condition is better verified for increasing *M*. The following approximation, therefore, holds for large *M*

$$C_{\varepsilon}^{\text{SC}}(\overline{\gamma}) - C(\overline{\gamma}) \simeq \log_2 \ln \frac{1}{1 - \varepsilon^{1/M}}.$$
 (30)

This means that the growth is as $\log_2 \ln M$, hence significantly slower than MRC.

Unlike MRC, we cannot recognize an array gain in SC due to the fact that in the absence of fading the SNR at the output of the combiner is $\overline{\gamma}$ for every *M*. However, considering the average SNR $\overline{\gamma}_s$ in (8), we can identify a gain at the output of the combiner. Using $\overline{\gamma} = \overline{\gamma}_s / (\sum_{\ell=1}^M 1/\ell)$ in (27), the outage capacity for SC can be expressed as

$$C_{\varepsilon}^{\rm SC}(\overline{\gamma}_{\rm s}) = C\left(1 + \overline{\gamma}_{\rm s} \frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}}\right). \tag{31}$$

Considering the difference with respect to the capacity of the reference AWGN channel with SNR $\overline{\gamma}_{s}$, we obtain

$$C_{\varepsilon}^{\text{SC}}(\overline{\gamma}_{\text{s}}) - C(\overline{\gamma}_{\text{s}}) = \log_2 \frac{1 + \overline{\gamma}_{\text{s}} \frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}}}{1 + \overline{\gamma}_{\text{s}}}.$$
 (32)

As shown below, one has

$$\lim_{M \to +\infty} \frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}} = 1$$
(33)

and, therefore, the capacity gap $C_{\varepsilon}^{SC}(\overline{\gamma}_s) - C(\overline{\gamma}_s)$ approaches zero from below for large diversity order, i.e., the outage capacity with SC approaches the benchmark specified by the reference AWGN channel with SNR $\overline{\gamma}_s$. To show (33), the following approximation of the partial sum of the divergent harmonic series can be used

$$\sum_{\ell=1}^{M} \frac{1}{\ell} \simeq \ln M + k_1 + k_M \tag{34}$$

where $k_1 \simeq 0.57$ is the Euler–Mascheroni constant and $k_M \rightarrow 0$ as *M* increases [18, Chap. 5]. Using (29) and (34), one has

$$\lim_{M \to +\infty} \frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}}$$

$$= \lim_{M \to +\infty} \frac{1}{\ln M} \ln \left(\frac{M}{-\ln \varepsilon}\right)$$

$$= \lim_{M \to +\infty} 1 - \frac{\ln(-\ln(\varepsilon))}{\ln M}$$

$$= 1.$$
(35)

To analyze the outage capacity for large diversity order, let us consider a sufficiently large SNR, i.e., $\overline{\gamma}_{\rm s} \gg 1$ and $\overline{\gamma}_{\rm s} \ln(1/(1 - \varepsilon^{1/M}) / \sum_{\ell=1}^{M} (1/\ell)) \gg 1$, such that the following approximation holds

$$C_{\varepsilon}^{\text{SC}}(\overline{\gamma}_{\text{s}}) - C(\overline{\gamma}_{\text{s}}) \simeq \log_2\left(\frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}}\right)$$
(36)

For large *M*, this expression can be approximated using (35) and the fact that $\ln(1 + x) \simeq x$ for $|x| \simeq 0$ as

$$C_{\varepsilon}^{\rm SC}(\overline{\gamma}_{\rm s}) - C(\overline{\gamma}_{\rm s}) \simeq \frac{1}{\ln 2} \left(-\frac{\ln(-\ln \varepsilon)}{\ln M} \right).$$
 (37)

Using the same Taylor series expansion used in the derivation of (29), one obtains that $C_{\varepsilon}^{SC}(\overline{\gamma}_{s})$ approaches the benchmark $C(\overline{\gamma}_{s})$ from below as ln *M*. Note that the second high-SNR condition behind (36) is also well behaved for increasing *M* since

$$\overline{\gamma}_{s} \underbrace{\frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}}}_{\rightarrow 1 \text{ for } M \rightarrow +\infty} \gg 1.$$
(38)

Finally, by similar arguments one can show that the ratio $C_{\varepsilon}^{\text{SC}}(\overline{\gamma}_{s})/C(\overline{\gamma}_{s})$ approaches 1 from below for large values of *M*. At low SNR, a well behaved approximation is

$$\frac{C_{\varepsilon}^{\rm SC}}{C(\overline{\gamma}_{\rm s})} \simeq \frac{1}{\sum_{\ell=1}^{M} 1/\ell} \ln \frac{1}{1 - \varepsilon^{1/M}} \tag{39}$$

which approaches 1 from below as $(\ln M)^{-1}$.

3.2. MISO

Since MRT and ST with N branches in MISO systems are equivalent to, respectively, MRC and SC with N branches in SIMO systems as per the results in Sections 2.1 and 2.2, the analysis in Section 3.1 is also valid here provided M is replaced by N.

3.3. MIMO

The analysis in Section 3.1 can be extended to massive MIMO scenarios with *N* transmit and *M* receive antennas used to pursue full diversity. In particular, we consider the optimal transmit beamforming and receive combining described in Section 2. The analysis for STC is not given, since it is equivalent to those for SC (in SIMO channels) and ST (in MISO channels) presented in Sections 3.1 and 3.2, respectively, provided the number of antennas is *MN*.

The SNR at the output of the combiner γ_m in (2) can be upper and lower bounded as follows. For any realization of the channel matrix **H**, its largest squared singular value can be upper and lower bounded by the sum and the average of all the squared singular values, respectively. In other words

$$\frac{1}{R_H} \sum_{i=1}^{R_H} \sigma_i^2 \le \sigma_{\max}^2 \le \sum_{i=1}^{R_H} \sigma_i^2$$
(40)

where R_H is the rank of **H**. Since $R_H \le \min\{M, N\}$, a further lower bound is obtained as

$$\frac{1}{\min\{M,N\}} \sum_{i=1}^{R_{H}} \sigma_{i}^{2} \le \sigma_{\max}^{2} \le \sum_{i=1}^{R_{H}} \sigma_{i}^{2}.$$
(41)

Moreover, it is well known that [19, Chap. 3]

$$\sum_{i=1}^{\kappa_{H}} \sigma_{i}^{2} = \|\boldsymbol{H}\|_{\mathrm{F}}^{2}$$
(42)

where $\|\boldsymbol{H}\|_{F}$ denotes the Frobenius norm of the channel matrix \boldsymbol{H} . Using (2) and (41), one finally obtains

$$\underbrace{\frac{\rho}{\min\{M,N\}} \|\boldsymbol{H}\|_{\mathrm{F}}^{2} \leq \gamma_{\mathrm{m}} \leq \underbrace{\rho \|\boldsymbol{H}\|_{\mathrm{F}}^{2}}_{\gamma_{\mathrm{m}}^{\mathrm{L}}} \qquad (43)$$

where the random lower and upper bounds to γ_m have been introduced as γ_m^L and γ_m^U , respectively. The distribution of the SNR γ_m in (43) is not known, but we

The distribution of the SNR γ_m in (43) is not known, but we know the distributions of its upper and lower bounds γ_m^U and γ_m^L , respectively. First, one should observe that, given two random variables *X* and *Y* such that $X \leq Y$ for any realizations, their CDFs are related as $F_X(x) \geq F_Y(x)$ [20]. Moreover, since $\gamma_m^U = \rho \|\boldsymbol{H}\|_F^2$ and $\gamma_m^L = \gamma_m^U / \min\{M, N\}$, they have the same distribution of $\|\boldsymbol{H}\|_F^2$. Recalling that

$$\|\boldsymbol{H}\|_{\rm F}^2 = \sum_{i=1}^M \sum_{j=1}^M |h_{ij}|^2 \tag{44}$$

the squared Frobenius norm of a random matrix with i.i.d. Gaussian entries is the sum of *MN* i.i.d. terms with exponential distribution, or equivalently the sum of *2MN* squared i.i.d. zero-mean Gaussian random variables. This means that, similarly to the MRC case in Section 3.1, for i.i.d. Rayleigh fading the distribution of $\|\boldsymbol{H}\|_F^2$ is chi-square with *2MN* degrees of freedom. Therefore, $\gamma_m^U = \rho \|\boldsymbol{H}\|_F^2$ and $\gamma_m^L = \gamma_m^U / \min\{M, N\}$ have the same distribution but for their mean value parameters, which are discussed in the following.

To proceed, it is convenient to set up a normalization condition on the channel matrix **H** by assuming its i.i.d. zero-mean entries have unit variance. This normalization does not limit the generality of the following discussion because all the considered SNRs scale with this variance accordingly. Under this normalization

$$\mathbb{E}\left\{\|\boldsymbol{H}\|_{\rm F}^{2}\right\} = \sum_{i=1}^{M} \sum_{j=1}^{N} \mathbb{E}\left\{|h_{ij}|^{2}\right\} = MN.$$
(45)

Using (43), the average SNR at the input of the demodulator can be bounded as

$$\underbrace{\rho \max\{M, N\}}_{\overline{\gamma}_{m}^{L}} \leq \overline{\gamma}_{m} \leq \underbrace{\rho M N}_{\overline{\gamma}_{m}^{U}}$$
(46)

where we used the fact that, given two random variables *X* and *Y* with $X \leq Y$ for any realizations, their means are related as $\mathbb{E}\{X\} \leq \mathbb{E}\{Y\}$ [20] and we have defined the means $\overline{\gamma}_m^L = \mathbb{E}\{\gamma_m^L\}$ and $\overline{\gamma}_m^U = \mathbb{E}\{\gamma_m^U\}$.

Based on the above setting, we can define lower and upper bounds on the CDF of the SNR γ_m , denoted respectively as $F_{\ell}(\cdot)$ and $F_u(\cdot)$, as chi-square with 2*MN* degrees of freedom and average per-branch SNRs $\overline{\gamma}^U$ and $\overline{\gamma}^L$, respectively defined as

$$\bar{\rho}^{\rm U} = \rho \tag{47}$$

$$\overline{\gamma}^{\mathsf{L}} = \frac{\rho}{\min\{M, N\}}.$$
(48)

These CDFs can be expressed by (15) with *M* replaced by *MN* and $\overline{\gamma}$ replaced by $\overline{\gamma}^{U}$ and $\overline{\gamma}^{L}$, respectively. Hence the outage probability can be bounded by these CDFs.

We can now bound the outage capacity of the MIMO diversity channel, using (14), as

$$C_{\varepsilon}^{\mathsf{L}}(\overline{\gamma}_{\mathsf{m}}^{\mathsf{L}}) \le C_{\varepsilon}^{\mathsf{MIMO}}(\overline{\gamma}_{\mathsf{m}}) \le C_{\varepsilon}^{\mathsf{U}}(\overline{\gamma}_{\mathsf{m}}^{\mathsf{U}})$$
(49)

with

ī

$$C_{\varepsilon}^{\mathsf{U}}(\overline{\gamma}_{\mathsf{m}}^{\mathsf{U}}) = C(F_{\ell}^{-1}(\varepsilon)) = \log_2\left(1 + F_{\ell}^{-1}(\varepsilon)\right)$$
(50)

$$C_{\varepsilon}^{\mathsf{L}}(\overline{\gamma}_{\mathsf{m}}^{\mathsf{L}}) = C(F_{\mathsf{u}}^{-1}(\varepsilon)) = \log_2\left(1 + F_{\mathsf{u}}^{-1}(\varepsilon)\right).$$
(51)

We can conclude that the outage capacity of the MIMO channel with full diversity is upper and lower bounded by that of the MRC SIMO channel with *MN* antennas and per-branch average SNRs $\overline{\gamma}^{U}$ and $\overline{\gamma}^{L}$, respectively. This implies that the analysis in Section 3.1 for MRC allows us to derive the above bounds, provided the correct diversity order and SNRs are considered.

These bounds may be reasonably tight if $\min\{M, N\}$ is small, i.e., if a large number of antennas is used at one side only, either transmitter or receiver. This case may be of interest to extend the previous analysis of SIMO and MISO channels to a cellular scenario in which the mobile terminals are equipped with a small number of antennas, whereas the base station uses a large antenna array. However, for doubly massive channels in which both *M* and *N* are large, $\min\{M, N\}$ is large and the bounds become loose.

To derive a capacity benchmark useful for the doubly massive MIMO diversity channel, we may resort to the asymptotic results in [21], which show that the largest squared singular value if M and N are both large, but their ratio y = M/N is fixed, approaches

$$\sigma_{\rm max}^2 \to 2(1+\sqrt{y})^2 N. \tag{52}$$

This implies that

$$\overline{\gamma}_{\rm m} \to \rho \, 2(1 + \sqrt{y})^2 N$$
 (53)

and, therefore, the outage capacity tends to that of MRC with $2(1 + \sqrt{y})^2 N$ antennas.

4. Numerical results

We now present numerical results on the analytical framework presented in Section 3. We consider two representative values of high and low outage probabilities, namely $\varepsilon = 10^{-1}$ and $\varepsilon = 10^{-3}$, respectively. In Section 4.1, we focus on the high-SNR regime, where the capacity gap is a representative performance indicator, as it describes the gap of the outage capacity of interest

Fig. 3. Capacity gap with respect to the benchmark $C(\overline{\gamma}_m)$, as a function of M, for the SIMO channel with MRC and various (large) values of SNR $\overline{\gamma}_m$ and outage probability ε . The results obtained by numerical inversion of the SNR CDF are compared with the GA.

with respect to the proper benchmark capacity of the reference AWGN channel. In Section 4.2, we discuss the low-SNR regime where the capacity ratio is of interest, as it provides the outage capacity of interest in terms of fraction of the capacity of the suitable benchmark AWGN channel.

4.1. High-SNR analysis

In Fig. 3, the capacity gap with respect to the AWGN channel with SNR $\overline{\gamma}_{\rm m}$ is shown, as a function of *M*, for the SIMO channel with MRC and various (large) values of SNR $\overline{\gamma}_{\rm m}$ and outage probability ε . The results obtained by numerical inversion of the SNR CDF are compared with the GA. All theoretical predictions are confirmed—in particular, the larger the number of antennas, the closer to zero the capacity gap. It is worth noting the slow convergence of this gap as $M^{-1/2}$. As expected, the smaller the outage probability, the worse the performance. Finally, note that for large values of *M*, the GA well predicts the system performance.

In Fig. 4, the capacity gap with respect to the AWGN channel with SNR $\overline{\gamma}_s$, as a function of M, is shown for the SIMO channel with SC and various (large) values of SNR $\overline{\gamma}_s$ and outage probability ε . Similar conclusions as in MRC can be drawn for SC. The curves for increasing value of SNR approach the benchmark $C(\overline{\gamma}_s)$ as predicted by (36). As M increases, a slow growth can be observed. This means that the benchmark can only be approached for realistic values of M except for a gap. As an example, considering $\varepsilon = 10^{-3}$, $C_{\varepsilon}^{SC} - C(\overline{\gamma}_s) \simeq -0.94$ b/s/Hz for M = 100. Increasing M from 100 to 1000 leads to a reduction in the capacity difference to approximately -0.59. Further increasing M to 10000 leads to a gap of approximately -0.43.

As observed in Section 3.2, the results in Figs. 3 and 4 are also valid for the MISO channel with MRT and ST with *M* transmit antennas, respectively.

Fig. 5 shows the outage capacity, as a function of the SNR ρ , for the massive MIMO diversity channel with $\varepsilon = 10^{-1}$ and various values of *N* and *M*.² Upper and lower bounds (solid and dashed lines), benchmarks (marks), and simulation results are shown. In particular, the AWGN benchmarks are given by the capacity $C(\overline{\gamma}_{\rm m}^{\rm L})$ and $C(\overline{\gamma}_{\rm m}^{\rm U})$, where $\overline{\gamma}_{\rm m}^{\rm L}$ and $\overline{\gamma}_{\rm m}^{\rm U}$ are related to ρ

Fig. 4. Capacity gap with respect to the benchmark $C(\overline{\gamma}_s)$, as a function of M, for the SIMO channel with SC and various (large) values of SNR $\overline{\gamma}_s$ and outage probability ε .

Fig. 5. Outage capacity, as a function of SNR, for the massive MIMO diversity channel with $\varepsilon = 10^{-1}$ and various values of *N* and *M*. Upper and lower bounds (solid and dashed lines), benchmarks (marks), and simulation results are shown.

as in (46). The limit from [21] is given by the outage capacity of the MRC channel (computed with the GA since *M* and *N* are both large) with SNR $\overline{\gamma}_m$ in (53). As one can see, for all the considered scenarios, upper and lower bounds $C_{\varepsilon}^{U}(\overline{\gamma}_m^{U})$ and $C_{\varepsilon}^{L}(\overline{\gamma}_m^{L})$ are close to the benchmarks $C(\overline{\gamma}_m^{U})$ and $C(\overline{\gamma}_m^{L})$. Moreover, for small values of *N*, the bounds are tight and the performance is well predicted. In the doubly massive case N = M = 100, the bounds are loose and the outage capacity is also estimated by Monte Carlo simulations over 10^6 independent runs. It can be observed that the performance is well predicted by the asymptotic benchmark from [21]. Simulations are not provided for the other cases, since upper and lower bounds are close to each other and predict well the true performance. These simulations were indeed performed and found in excellent agreement with the bounds.

4.2. Low-SNR analysis

In Fig. 6, the capacity ratio is shown, as a function of *M*, for the SIMO channel with MRC and various (low) values of SNR

 $^{^2}$ Similar considerations hold for other values of the outage probability.

Fig. 6. Capacity ratio, as a function of *M*, for the SIMO channel with MRC and various (low) values of SNR $\overline{\gamma}_m$ and outage probability ε . The results obtained by numerical inversion of the SNR CDF are compared with the GA.

Fig. 7. Capacity ratio, as a function of *M*, for the SIMO channel with SC and various (low) values of SNR $\overline{\gamma}_s$ and outage probability ε .

 $\overline{\gamma}_{\rm m}$ and outage probability ε . The results obtained by numerical inversion of the SNR CDF are compared with the GA. Similar conclusions as for the capacity gap in Fig. 3 can be drawn. One should observe that for large values of *M*, the GA well predicts the system performance in this case as well. In particular, at low SNR the capacity ratio based on the GA approaches 1 as $M^{-1/2}$ for realistic values of *M*. Note that compared with the reference value $C(\overline{\gamma}_{\rm m})$ the outage capacity is only a fraction and the loss is more evident with respect to the high-SNR case of MRC shown in Fig. 3.

In Fig. 7, the capacity ratio is shown, as a function of *M*, for the SIMO channel with SC and various (low) values of SNR $\overline{\gamma}_s$ and outage probability ε . As for the capacity gap in Fig. 4, as *M* increases, very slow (logarithmic) growth can be observed and the benchmark cannot be approached in practice. Moreover, the achievable fraction of the reference capacity is lower than for MRC, meaning that SC is less effective in the low-SNR regime.

Fig. 8. Outage capacity, as a function of SNR, for the massive MIMO diversity channel with $\varepsilon = 10^{-1}$ and various values of *N* and *M*. Upper and lower bounds (solid and dashed lines), benchmarks (marks), and simulation results are shown.

As per Section 3.2, the results in Figs. 6 and 7 are also valid for the MISO channel with MRT and ST with *M* transmit antennas, respectively.

In Fig. 8, the outage capacity in the low SNR regime is shown for the massive MIMO diversity channel with $\varepsilon = 10^{-1}$ and various values of *N* and *M*. Upper and lower bounds (solid and dashed lines), benchmarks (marks), and simulation results are shown as in Fig. 5. Similar considerations to those in Fig. 5 for the high-SNR regime are valid for the low-SNR regime.

5. Concluding remarks

In this paper, we presented an analysis of the outage capacity for the massive MIMO diversity channel subject to i.i.d. Rayleigh fading. We started from a SIMO channel and presented a numerical solution and a GA for MRC. An exact analysis was presented for SC. The analysis was also shown to be valid for the MISO channel with MRT and ST. The analysis was then extended to the massive MIMO diversity channel, showing that its outage capacity can be upper and lower bounded by that of an MRC system with a proper number of antennas. Moreover, an asymptotic benchmark was provided for the massive MIMO diversity channel and confirmed by simulation. Our results show that, if the number of antennas is sufficiently large, the outage capacity of each considered diversity channel approaches that of the reference AWGN channel with properly defined values of SNR for large but realistic numbers of antennas.
